SUMMARY

Nivolumab is a programmed death receptor-1 blocking monoclonal antibody which has been approved by United States Food and Drug Administration for patients with metastatic non-squamous non-small cell lung cancer. Endocrinopathies like thyroid dysfunction and adrenal insufficiency are its known immune related adverse effects. Hypophysitis is very rare and usually presents with minimal symptoms. We report development of hypophysitis in an 84-year-old female patient who developed a range of symptoms (fatigue, headache, nausea) as well as laboratory confirmation of both central hypothyroidism and central adrenal deficiency which is unusual in cases of nivolumab induced hypophysitis. The patient had well differentiated adenocarcinoma of the left upper lobe of the lung. She underwent wedge resection followed by chemotherapy and was started on nivolumab due to recurrence. After 14 cycles of nivolumab, she started complaining of intense fatigue. She was found to have central thyroid deficiency and was started on levothyroxine. But her symptoms did not improve. Then she underwent adrenocorticotropic hormone stimulation test which showed central adrenal deficiency, but her brain magnetic resonance imaging did not reveal any pituitary or sellar changes. A diagnosis of nivolumab induced hypophysitis was made, based on clinical grounds and hormonal profile and she was started on oral steroids. She responded dramatically to this steroidal therapy within four weeks of its initiation and her immunotherapy with nivolumab was restarted.

1. Introduction

Nivolumab is a monoclonal antibody of immunoglobulin G4 type which targets the programmed death-1 (PD-1) receptor. It was approved by United States Food and Drug Administration (FDA) in October 2015 for patients with metastatic non-squamous non-small cell lung cancer (NSCLC) based on the CheckMate 057 trial that showed improvement in overall survival as compared to docetaxel in patients who progressed on or after platinum-based chemotherapy. It has also been approved for the treatment of advanced melanoma, malignant pleural mesothelioma, advanced renal cell carcinoma, classical Hodgkin’s lymphoma, advanced squamous cell carcinoma of head and neck, urothelial carcinoma, metastatic colorectal cancer, hepatocellular carcinoma, and advanced esophageal squamous cell carcinoma (1,2). The main immune-related adverse events (irAEs) associated with nivolumab include diarrhea, colitis, hepatitis, skin toxicities and endocrinopathies such as hypophysitis and thyroid dysfunction (3). Although thyroid dysfunction is a common adverse effect of nivolumab, hypophysitis is rare with an incidence of less than 1% and only a handful cases of nivolumab induced hypophysitis in patients with NSCLC have been described in literature (4-6). Usually, such cases present with less symptoms and radiological features as compared to other immunotherapy related hypophysitis (5,6). We present a novel case of an elderly patient with recurrent NSCLC who was diagnosed with nivolumab induced hypophysitis based on clinical suspicion due to her hormonal profile and a range of symptoms which she developed during nivolumab immunotherapy.

2. Case Report

An 84-year-old Caucasian female, who was first diagnosed with well differentiated adenocarcinoma of the left upper lobe of lung in 2009, underwent left
It has been seen that nivolumab immunotherapy was restarted and the low dose prednisolone along with same dose levothyroxine was continued till the end of therapy.

### 3. Discussion

Hypophysitis is an acute or chronic inflammation of the pituitary gland. It is a rare condition in the general population and its incidence has not yet been quantified. However, less than 1% of surgically treated pituitary lesions demonstrate histological features of hypophysitis (7). Autoimmune hypophysitis, which is a subtype, has a prevalence of about 5 per million and an annual incidence of 1 in 7 to 9 million (8). Immunotherapy-associated hypophysitis is commonly associated with headache and anterior hypopituitarism. Anterior hypopituitarism presents with a characteristic but atypical pattern of deficiency of ACTH followed by TSH, gonadotrophins and prolactin deficiency or hyperprolactinemia (9). The degree of pituitary enlargement is generally mild which goes undetected on MRI or is completely absent, and compression of the optic apparatus is extremely rare (5,6,9).

Prior to the nivolumab, hypophysitis was relatively common in patients treated with ipilimumab, a human monoclonal antibody against the cytotoxic T-Lymphocyte antigen 4 (CTLA-4 Ab), which was approved by the FDA in 2011 for the treatment of advanced melanoma (10-15). It has been seen that as compared to ipilimumab associated hypophysitis, nivolumab induced hypophysitis is still rare, is diagnosed late (median of 25 weeks) and is less commonly associated with any symptoms like headache or any pituitary changes detected on MRI (5,6). However, our patient presented with a range of symptoms (fatigue, headache, nausea) as well as laboratory confirmation of both central hypothyroidism and central adrenal deficiency which is unusual in cases of nivolumab induced hypophysitis. A review of the trial data of immune checkpoint-induced hypophysitis showed that the incidence of hypophysitis for ipilimumab was 0-17% (6,16,17) while the incidence was less for nivolumab (<1%) (7,18) and pembrolizumab (<1%) (7, 19).

In a retrospective analysis of 83 patients treated with immunotherapy to observe the immune checkpoint inhibitor related hypophysitis (irH), the irH was defined as (i) ACTH or TSH deficiency plus MRI changes or (ii) ACTH and TSH deficiencies plus headache/fatigue in the absence of MRI findings. As per this
definition, 62 patients had irH at initial evaluation and the most common symptom was fatigue (66%) followed by headache (60%). Central hypothyroidism and central adrenal insufficiency were seen in 94% and 69% patients, respectively and 77% of the irH patients had MRI changes like stalk thickening, suprasellar convexity, and heterogeneous enhancement of the pituitary gland. 48 out of 62 (77%) patients were on ipilimumab, 2/62 (3%) on tremelimumab, 3/62 (5%) on nivolumab, and 9/62 (15%) on a combination of both nivolumab and ipilimumab. When compared to therapies without ipilimumab, those with ipilimumab had a statistically significant association with irH (p < 0.01) and the median time interval from initiation of immunotherapy to development of irH was less for ipilimumab (9-12 weeks) as compared to nivolumab (30.4-37.7 weeks) (20).

Patients with irH have been treated with physiologic to high-dose glucocorticoids resulting in improvement of symptoms and pituitary function. In most patients, the steroids and other hormone replacements, like for thyroid, need to be continued till the end of immunotherapy or even after the end of immunotherapy as the recovery rate is variable. The chance of recovery of thyroidal axis is more than the adrenal or gonadal axis (5,6,9,20).

Our patient developed central hypothyroidism followed by central adrenal deficiency as evident by ACTH stimulation test. Her brain MRI did not show any significant finding, but she had history of episodes of headache, prolonged sleepiness, and nausea. Her presentation was novel for nivolumab induced hypophysitis and a diagnosis was made, based on clinical grounds and hormonal profile. She was started on glucocorticoids to which she responded well symptomatically which further supported our diagnosis. In almost all cases of immune mediated hypophysitis, the histopathological diagnosis of hypophysitis by biopsy of pituitary gland is never indicated due to increased risk-to-benefit ratio. Hence, a high degree of clinical suspicion is required for its timely diagnosis.

4. Conclusion

Immunotherapy induced hypophysitis is a rare condition and has frequently been described with Anti-CTLA4 agents like ipilimumab, but it is rare with Anti-PD1 agents like nivolumab and usually presents with less symptoms. A normal MRI of the brain does not exclude hypophysitis. Therefore, a high degree of clinical suspicion and multidisciplinary team involving medical oncologists, clinical pharmacologists, endocrinologists, and radiologists is required to diagnose such cases.
